Summary

- Investigated the impact of alternative ways of imposing soil moisture stress on plants. Results so far:
 - **Biochemical** treatment: moderately thirsty, moderately productive, moderately prone to stomatal suicide (via temperature, not via VPD), largest drop in internal CO₂
 - **Stomatal** treatment: water-conserving, most productive, prone to stomatal suicide (via temperature and VPD), least drop in internal CO₂
 - **Mesophyll** treatment: thirsty, but not productive, runs cooler (but hot during heat waves), least sensitive to VPD, largest drop in internal CO₂
 - **“Combination”** (C6) treatment: bears a strong stomatal fingerprint
- Sensitivity to the soil water stress treatment is consistent over a range of JULES versions 2.2, 4.2 and 4.4. However:
 - Used a constant LAI forcing, which is not very realistic for anomalous years such as 2003
 - Soil hydrology is still rather naïve (e.g. only 4 layers)
 - Need to combine with all other new developments in JULES
